## Abstract

*EuroAmerican land use and its legacies have transformed forest structure and composition in many regions of the United States. More accurate reconstructions of historical states are critical to understanding the processes governing past, current, and future forest dynamics.*

*We develop and present a new dataset of gridded (8x8km) estimates of pre-settlement (1800s) vegetation from the upper Midwestern United States (Minnesota, Wisconsin, and most of Michigan) using the 19<sup>th</sup> Century Public Land Survey (PLS) records, with estimates of relative composition for 26 tree genera and total biomass, stem density, and basal area. We present new approaches to correct for variations in surveyor sampling by applying spatially varying correction factors that accommodate alternate sampling designs, azimuthal censoring, and biases in tree selection. We applied these estimates to map forest, prairie and savanna distributions, and to reconstruct spatial patterns in forest composition and structure, which we compare to modeled potential vegetation maps that are widely used by terrestrial ecosystem modelers as historic baselines. We compare pre-settlement to modern forests using Forest Inventory and Analysis (FIA) data, both with respect to structural changes and the prevalence of forests with no current or past analogs.*

*Stem density and total basal area are higher in contemporary forests than in settlement-era forests, but aboveground biomass was higher in settlement-era forests, in part because individual settlement-era trees were larger on average. Modern forests are more homogeneous than settlement-era forests, and ecotonal gradients are less sharp today than in the past. Novel forest represent 28% of all FIA cells, with no close analog to settlement-era forest composition, while 25% of pre-settlement forests no longer exist in a modern context. The loss of PLS forest types is centered around the forests of the Tension Zone, concentrated particularly in hemlock- and beech-dominated forests between deciduous and evergreen forests. This loss changes the structure of major ecotones across the region, including forest-prairie, sub-boreal-deciduous and mixed-wood to prairie ecotones. Novel FIA forest assemblages are distributed evenly across the region, representing a broad-scale homogenization of forest composition and structure that is strongly influenced by current and historic land use. All datasets and open-source analytical scripts are publicly available, providing a benchmark for future analyses, and work is underway to extend these settlement-era reconstructions across the northeastern US forests.*

**Key Words:** forest composition, land use change, paleoecology, public land survey

## Introduction:

The composition, demography, and structure of forests in eastern North America have changed continuously over the last millennium, driven by human land use (Foster et al. 1998, Ramankutty and Foley 1999, Ellis and Ramankutty 2008, Thompson et al. 2013, Munoz et al. 2014) and climate variability (Umbanhowar Jr et al. 2006, Hotchkiss et al. 2007, Booth et al. 2012, Pederson et al. 2014). While human effects have always been a component of these systems, the EuroAmerican settlement and industrialization period have increased anthropogenic effects by orders of magnitude (Brugam 1978, Mcandrews 1988, Fuller et al. 1998). Legacies of post-settlement land use in the upper Midwest (Grossmann and Mladenoff 2008) and elsewhere have been shown to persist at local and regional scales (Foster et al. 1998, Dupouey et al. 2002, Etienne et al. 2013), and nearly all North American forests have been affected by the intensification of land use in the past three centuries. Hence, observed ecological processes in North American forests reflect both the greater anthropogenic impacts of the post-EuroAmerican period and natural influences at decadal to centennial scales. These dual influences pose the challenge that natural processes of succession, senescence and replacement of tree species in forests may be masked, or heavily modified by historically recent land use change.

At a regional scale many forests in the upper Midwest (*i.e.*, Minnesota, Wisconsin and Michigan) now have decreased species richness and functional diversity relative to forests of the pre-Euro-American settlement (hereafter pre-settlement) period (Schulte et al. 2007, Hanberry et al. 2012a, Li and Waller 2014) due to near complete logging. For example, forests in Wisconsin are in a state of regrowth, with an unfilled carbon sequestration potential of 69 TgC (Rhemtulla et al. 2009a) as a consequence of these extensive land cover conversions and subsequent partial recovery. The upper Midwestern United States represents a unique

ecological setting, with multiple major ecotones, including the prairie-forest boundary, historic savanna, and the tension zone between southern deciduous forests and northern evergreen forests. The extent to which these ecotones have shifted, and their extent both prior to and following settlement at a regional scale is of critical importance to biogeochemical and biogeophysical vegetation-atmosphere feedbacks (Matthes et al. in revision), carbon sequestration (Rhemtulla et al. 2009a), and regional management and conservation policy (Radeloff et al. 2000, Fritschle 2008, Knoot et al. 2010, Gimmi and Radeloff 2013).

At land use change at the local and state-level has been shown to affect both the structure and composition for forests in the Midwestern United States (e.g. Schulte et al. 2007, ???). Homogenization and shifts in overall forest composition are evident, but the spatial extent and structure of this effect is less well understood. Studies in Wisconsin have shown differential patterns of change in the mixedwood and evergreen dominated north versus the southern driftless and hardwood south. Does this pattern of differential change extend to Minnesota and Michigan? To what extent are land-use effects common across the region, and where are responses ecozone specific? In particular has the extent of homogenization (Schulte et al. 2007) resulted in novel forest assemblages relative to pre-settlement baselines across the region, and the loss of pre-settlement forest types? Is the spatial distribution of these novel and lost forest types overlapping, or do they have non-overlapping extents?

Modern forest structure and composition data (e.g., from the United States Department of Agriculture - Forest Service's Forest Inventory and Analysis National Program, FIA; Gray et al. 2012) play a ubiquitous role in forest management, conservation, carbon accounting, and basic research on forest ecosystems and community dynamics. These recent surveys (the earliest FIA surveys began in the 1930s) can be extended with longer-term historical data to understand how forest composition has changed since Euro-American settlement. The Public Land Survey was largely carried out ahead of mass EuroAmerican settlement west and south of Ohio to provide for delineation and sale of the public domain beyond the original East Coast states (Stewart 1935, White 1983). Therefore ecological data can be derived that provides broad coverage of the United States prior to large-scale Euro-American settlement (*add references across the region*)(Almendinger 1996, Liu et al. 2011). In general, FIA datasets are systematically organized and widely available to the forest ecology and modeling community, whereas most PLS data compilations are of local or, at most, state-level extent. This absence of widely available data on settlement-era forest composition and structure limits our ability to understand and model the current and future processes governing forest dynamics at broader, regional scales. For example, distributional models of tree species often rely upon FIA or other contemporary observational data to build species-climate relationships that can be used to predict potential range shifts (Iverson and Prasad 1998, Iverson and McKenzie 2013). If land use change affects the shape of the realized niche then species distribution modeling, based on correlative models relating current extent to local climatic and edaphic factors, may have much weaker ability to interpret species responses to climate change than model diagnostics might indicate. Indeed, re-organization following land use change may result in shifts in species co-occurrence, and the development of novel ecosystems. If broad-scale reorganization is the norm following Euro-American settlement, then the conditions we have been studying as ecologists for the past century may indeed be novel relative to the 'pristine' conditions of the pre-settlement era.

Here we use survey data from the original Public Lands Surveys (PLS) in the upper Midwest to derive estimates of pre-settlement (ca. mid-late 1800s) forest composition, basal area, stem density, and biomass. This work builds upon prior digitization and classification of PLS data for Wisconsin (Manies and Mladenoff 2000, Schulte et al. 2002) and for parts of Minnesota (Friedman and Reich 2005, Hanberry et al. 2012a) and Michigan (USFS-NCRS <http://www.ncrs.fs.fed.us/gla/>). Most prior PLS-based reconstructions are for individual states or smaller extents (among others: Duren et al. (2012); Hanberry et al. (2012a); Rhemtulla et al. (2009a); Friedman and Reich (2005)] often with coarser spatial aggregations (Schulte et al. 2007, Hanberry et al. 2012a), although aggregation may also occur at the section (Rhemtulla et al. 2009a) or township scale (Kronenfeld et al. 2010). Our work develops new approaches to address major challenges to PLS data, including lack of standardization in tree species names, azimuthal censoring by surveyors, variations in sampling design over time, and differential biases in tree selection among different kinds of survey points within the survey design at any point in time. The correction factors developed here are spatially varying, allowing us to accommodate temporal and spatial variations in surveyor methods.

We aggregate point based estimates of stem density, basal area and biomass to an 8 x 8km grid to help reduce

local scale uncertainty, and classify forest types in the upper Midwest to facilitate comparisons between FIA and PLS data. We compare the PLS data to late-20th-century estimates of forest composition, tree stem density, basal area and biomass from FIA data. Using the gridded data we examine species co-occurrence and two spatial transects across the domain to understand the extent of change along forest ecotones at a broad spatial scale, and along well-understood ecotones from southern deciduous to northern evergreen forests and to the forest-prairie boundary. Using analog analyses, we identify lost forests that have no close compositional counterpart today and novel forests with no close historical analogs. This work provides insight into the compositional and structural changes between historic and contemporary forests, while setting the methodological foundation for a new generation of settlement-era vegetation maps for the northern forests of the Eastern US.

## Methods:

### Public Lands Survey Data: Assembly, and Standardization

The PLS was designed to facilitate the division and sale of federal lands from Ohio westward and south. The survey created a 1 mile<sup>2</sup> (2.56 km<sup>2</sup>) grid (sections) on the landscape. At each section corner, a stake was placed as the official location marker. To mark these survey points, PLS surveyors recorded tree stem diameters, measured distances and azimuths of two to four trees near sample points and identified tree taxa using common (and often regionally idiosyncratic) names. PLS data thus represent measurements by hundreds of surveyors from 1832 until 1907, with changing sets of instructions over time (Stewart, 1979).

The PLS was undertaken to survey land prior to assigning ownership (Stewart 1935, White 1983), replacing earlier town proprietor surveys (TPS) used for the northeastern states (Cogbill et al. 2002, Thompson et al. 2013). The TPS provided estimates of relative forest composition at the township level, but no structural attributes. The PLS produced spatially explicit point level data, providing information about tree spacing and diameter across an extensive region. PLS notes include tree identification at the plot level, disturbance (Schulte and Mladenoff 2005) and other features of the pre-settlement landscape. However, uncertainties exist within the PLS and township level dataset (Bourdo 1956).

Ecological uncertainty in the PLS arises from dispersed spatial sampling within the dataset (fixed sampling every 1 mile), precision and accuracy in converting surveyor's use of common names for tree species to scientific nomenclature (Mladenoff et al. 2002), digitization of the original survey notes, and surveyor bias during sampling (Bourdo 1956, Manies et al. 2001, Schulte and Mladenoff 2001, Liu et al. 2011). Estimates vary regarding the ecological significance of surveyor bias. Terrail *et al.* (2014) show strong fidelity between taxon abundance in early land surveys versus old growth plot surveys. Liu *et al.* (2011) estimate the ecological significance of some of the underlying sources of bias in the PLS and show ecologically significant (>10% difference between classes) bias in species and size selection for corner trees, however the authors also indicate that the true sampling error cannot be determined, particularly since these historic ecosystems are largely lost to us. Kronenfeld and Wang (2007), working with Historical Land Cover datasets in western New York indicate that direct estimates of density using plotless estimators may be off by nearly 37% due to angular bias bias (*i.e.*, tendency of surveyors to avoid trees close to cardinal directions), while species composition estimates may be adjusted by between -4 to +6%, varying by taxon, although Kronenfeld (2014) shows adjustments of less than 1%. These biases can be minimized by appropriate analytical decisions; many efforts over the years have assessed and corrected for the idiosyncrasies of the original surveyor data to minimize sampling bias (Manies et al. 2001, Kronenfeld and Wang 2007, Bouldin 2008, Hanberry et al. 2011, 2012a, 2012b, Liu et al. 2011, Williams and Baker 2011, Cogbill et al. in prep). And, even given these caveats, PLS records remain the best source of data about both forest composition and structure in the United States prior to Euro-American settlement.

This analysis builds upon and merges previous state-level efforts to digitize and database the point-level PLS data for Wisconsin, Minnesota and the Upper Peninsula and upper third of the Lower Peninsula of Michigan. These datasets were combined using spatial tools in R (package *rgdal*: Bivand et al. 2014, Team 2014) to form a common dataset for the upper Midwest (Figure 1) using the Albers Great Lakes and St Lawrence projection (see code in Supplement 1, file: *step\_one\_clean\_bind.R*; proj4: *+init:EPSG:3175*).

We took several steps to standardize the dataset and minimize the potential effects of surveyor bias upon estimates of forest composition, density, and biomass. All steps are preserved in in the supplementary R code (Supplement 1: *step\_one\_clean\_bind.R*). First, we excluded line and meander trees (i.e. trees encountered along survey lines, versus trees located at section or quarter corners) because surveyor selection biases appear to have been more strongly expressed for line trees, the non-random habitat preferences of meander trees (Liu et al. 2011), and the inherent differences in sampling design between line, meander and corner points. We used only the closest two trees at each corner point because the third and fourth furthest trees have stronger biases with respect to species composition and diameter (Liu et al. 2011). Corner points were used only if 1) there were at least two trees at a survey point, 2) the two trees were from different quadrants (defined by the cardinal directions), and 3) there were valid azimuths to the trees (a defined quadrant with an angle between 0 and 90) and valid diameters (numeric, non-zero).

Many species-level identifications used by PLS surveyors are ambiguous. Statistical models can predict the identity of ambiguous species (Mladenoff et al. 2002), but these models introduce a second layer of uncertainty into the compositional data, both from the initial surveyors' identification, and from the statistical disambiguation. Given the regional scale of the analysis, and the inherent uncertainty in the survey data itself, we chose to avoid this added layer of taxonomic uncertainty, and retained only genus-level identification (Supplement 2, *Standardized taxonomy*). In areas of open prairie or other treeless areas, e.g. southwestern Minnesota, surveyors recorded distances and bearings to 'Non Tree' objects. When points were to be located in water bodies the point data indicates 'Water'. Points recorded "No Tree" are considered to have been extremely open, with an estimated point level stem density of 0 stems/ha. We based our estimates on terrestrial coverage, so water cells are excluded completely. Hence, absence of trees at water points does not reduce overall terrestrial stem density.

Digitization of the original surveyor notebooks introduces the possibility of transcription errors. The Wisconsin dataset was compiled by the Mladenoff lab group, and has undergone several revisions over the last two decades in an effort to provide accurate data (Manies and Mladenoff 2000, Radeloff et al. 2000, Mladenoff et al. 2002, Schulte et al. 2002, Liu et al. 2011). The Minnesota transcription error rate is likely between 1 and 5%, and the treatment of azimuths to trees varies across the dataset (Almendinger 1996). Michigan surveyor observations were transcribed to mylar sheets overlaid on State Quadrangle maps, so that the points were displayed geographically, and then digitized to a point based shapefile (Ed Schools, pers. comm.; Great Lakes Ecological Assessment. USDA Forest Service Northern Research Station. Rhinelander, WI. <http://www.ncrs.fs.fed.us/gla/>), carrying two potential sources of transcription error. Preliminary assessment of Southern Michigan data indicates a transcription error rate of 3 - 6%. To reduce errors associated with transcription across all datasets, we exclude sites for which multiple large trees have a distance of 1 link (20.12 cm) to plot center, trees with very large diameters (dbh > 100 in; 254 cm), plots where the azimuth to the tree is unclear, and plots where the tree is at plot center but has a recorded azimuth. All removed plots are documented in the code used for analysis (Supplement 1: *step\_one\_clean\_bind.R*) and are commented for review.

## Data Aggregation

We binned the point data using an 64km<sup>2</sup> grid (Albers Gt. Lakes St Lawrence projection; Supplement 1: *base\_calculations.R*) to create a dataset that has sufficient numerical power for spatial statistical modeling and sufficient resolution for regional scale analysis (Thurman et al. in prep). This scale is smaller than the 100km<sup>2</sup> gridded scale used in Freidman and Reich (2005), but larger than township grids used in other studies (Rhemtulla et al. 2009a, Kronenfeld 2014) to provide a scale comparable to aggregated FIA data at a broader scale. Forest composition data is based on the number of individuals of each taxon (genera or plant functional types, PFTs) present at all points within a cell. Stem density, basal area and biomass are averaged across all trees at all points within the cell.

## Stem Density, Basal Area and Biomass Estimates

Estimating stem density, basal area, and biomass from PLS data requires various corrections to minimize sampling bias in the original surveyor measurements (Manies et al. 2001, Kronenfeld and Wang 2007, Bouldin 2008, Hanberry et al. 2011, 2012a, 2012b, Liu et al. 2011, Williams and Baker 2011, Cogbill et al. in prep). Survey sampling instructions changed throughout the implementation of the PLS in this region and differed between section and quarter section points, and between internal and external points within townships (White 1983, Liu et al. 2011). The changing plot geometry across the region thus precludes uniform methods for correcting for surveyor bias when aggregating from points to grids sampling geometry varies significantly among plots (Cogbill et al. in prep). Our approach allows for spatial variation in surveyor methods by applying spatially varying correction factors that are based on plot geometry, angle distributions and diameter censoring within the data set.

We estimate stem density (stems  $m^{-2}$ ) based on a modification of the distance-to-tree measurements for the two closest trees at each point (Morisita 1954) using explicit and spatially varying correction factors, modeled after the Cottam correction factor (Cottam and Curtis 1956), that accounts for variations in sampling designs over time and among surveyors. All code to perform the analysis is included in Supplement 3.

Stem density is calculated using a modified form of the Morisita equation. The original Morisita equation is expressed as:

$$d_i = \frac{q-1}{\pi \times n} \times \sum_{j=1}^q \frac{q}{(r_j)^2}$$

Here,  $d_i$  is the density estimate at point  $i$ ,  $q$  is the number of sectors sampled (all  $q = 2$ ),  $r_j$  is the distance from the plot center to tree  $j$  (in meters).

The modified form of the Morisita equations is expressed as:

$$d_i = \kappa \times \frac{q-1}{\pi \times n} \times \sum_{j=1}^q \frac{q}{(r_j)^2} \times \theta \times \zeta \times \phi$$

The modified form adds several parameters to adjust for departures from the standard point-centered quarter method assumed by Morisita and for several potential sources of surveyor bias when selecting trees. We account for variations in sample design, in particular the lack of a true point-centered quarter method, using  $\kappa$ , the modified Cottam correction factor. The parameter  $\theta$  accounts for deviation from the expected pair angle distribution associated with differences in plot geometry. As plots change from two trees in a  $180^\circ$  semi-circle (exterior points) to true point-centered quarters, the distribution of pair angles changes along with the sampled area. Our  $\theta$  estimates are empirically derived with  $\theta = 1$  representing a true point-quarter sampling design. The  $/theta$  values range from 0.71 to 1.27, with the value of  $/theta$  increasing as the proportion of the two closest trees with azimuthal pairs greater than  $90^\circ$  increases. This effectively accounts of sampling designs where closest trees must be in opposite halves, and increases the estimated stem density (when  $/theta > 1$ ) by accounting for the fact that potential closer trees are not sampled because of the plot design.

The parameter  $\zeta$  is used to correct for azimuthal censoring, because surveyors appear to censor certain azimuths (Kronenfeld and Wang 2007), particularly along cardinal directions of travel, a pattern that varies across plot types. In this model a  $\zeta = 1$  would be applied to sets of plots for which no azimuthal censoring is visible. Plots with a greater degree of censoring, particularly along the cardinal directions, obtain higher correction factors, up to 25% (Figure 2). The correction factor for  $/zeta$  ranges from 1.03 to 1.25 as censoring increases.

The last correction factor,  $\phi$ , is used to reduce the impact of sampling stems under 8" in diameter within a region, which would otherwise replace trees of larger diameters at greater distances, resulting in higher stem densities than expected if only trees  $> 8"$  were sampled. The correction for  $/phi$  effectively reduces the overall estimated stem density for trees over 8" in diameter, and ranges from 0.6 - 0.9. The full rationale for and calculation of these measures is described further in Cogbill *et al.* (in prep). Correction factors were calculated separately for different regions, years, internal versus external section points, and surveyor sampling designs (Table 1).

Basal area is calculated by multiplying the point-based stem density estimate by the average stem basal area from the reported diameters at breast height for the closest two trees at the point ( $n=2$ ). Aboveground dry biomass (Mg/ha) is calculated using the USFS FIA tree volume and dry aboveground biomass equations for the United States (Jenkins et al. 2004).

Biomass equations share the basic form:

$$m = \text{Exp}(\beta_0 + \beta_1 * \ln dbh)$$

where  $m$  represents stem biomass for an individual tree in kg.  $\beta_0$  and  $\beta_1$  are the parameters described in Table 2 and  $dbh$  is the stem diameter at breast height (converted to cm) recorded in the survey notes. The biomass estimates are summed across both trees at a survey point and multiplied by the stem density calculated at that point to produce an estimate of aboveground biomass reported in Mg/ha<sup>-1</sup> (Jenkins et al. 2004).

Matching PLSS tree genera to the species groups defined by Jenkins *et al.* (2004) is straightforward, placing the 22 genera used in this study into 9 allometric groups (Table 2). However, all maples are assigned to the generic “Hardwood” group since separate allometric relationships exist for soft and hard maple (Table 2). Biomass estimates for “Non tree” survey points are assigned 0 Mg/ha.

We use the stem density thresholds of Anderson and Anderson (1975) to discriminate prairie, savanna, and forest.

## FIA Stem Density, Basal Area and Biomass

The United States Forest Service has monitored the nation’s forests through the FIA Program since 1929, with an annualized state inventory system implemented in 1998 (Woudenberg et al. 2010). On average there is one permanent FIA plot per 2,428 ha of land in the United States classified as forested. Each FIA plot consists of four 7.2m fixed-radius subplots in which measurements are made of all trees >12.7cm dbh (Woudenberg et al. 2010). We used data from the most recent full plot inventory (2007-2011). The FIA plot inventory provides a median of 3 FIA plots per cell using the 64km<sup>2</sup> grid.

We calculated mean basal area (m<sup>2</sup>/ha), stem density (stems/ha), mean diameter at breast height (cm), and mean biomass (Mg/ha) for all live trees with dbh greater than 20.32cm (8in). Biomass calculations used the same set of allometric regression equations as for the PLS data (Jenkins et al. 2004).

## Gridding and Analysing PLS and FIA Data

Spatial maps of stem density, basal area and biomass were generated by averaging all PLS point or FIA plot estimates within a 64km<sup>2</sup> raster cell. Differences in sampling design between PLS and FIA data affect the partitioning of within-cell versus between-cell variance, but not the expected estimates. Most 64km<sup>2</sup> cells have one or a few intensively sampled FIA plots. Therefore at this scale of aggregation, the low density of FIA plots in heterogeneous forests could result in high within-cell variance and high between-cell variability. For the PLS points, stem density estimates are sensitive to trees close to the plot center. Point-level estimates with very high stem densities can skew the rasterized values, and it is difficult to distinguish artifacts from locations truly characterized by high densities. To accommodate points with exceptionally high densities we carry all values through the analysis, but exclude the top 2.5 percentile when reporting means and standard deviations in our analysis. PLS-based estimates are highly variable from point to point due to the small sample size, but have low variance across the landscape due to the uniform sampling pattern of the data. Thus while within-cell variance is expected to be high for the PLS point data, and spatial patterns are expected to be robust at the cell level. The base raster and all rasterized data are available as Supplement 3.

Standard statistical analysis of the gridded data, including correlations and regression, was carried out in R (Team 2014), and is documented in supplementary material that includes a subset of the raw data to allow reproducibility. Analysis and presentation uses elements from the following R packages: **ggplot2** (Wickham 2009a, 2009b), **gridExtra** (Auguie 2012), **igraph** (Csardi and Nepusz 2006), **mgcv** (Wood 2011), **plyr** (Wickham 2011), **raster** (Hijmans 2014), **reshape2** (Wickham 2007), **rgdal** (Bivand et al. 2014),

`rgeos` (Bivand and Rundel 2014), `sp` (Pebesma and Bivand 2005, Bivand et al. 2013), and `spdep` (Bivand 2014).

We identify analogues and examine differences in composition between and within PLS and FIA datasets using Bray-Curtis dissimilarity (`vegdist` in `vegan`; Oksanen et al. 2014) for proportional composition within raster cells using basal area measurements. For the purposes of this analysis we are interested only in the minimum compositional distance between a focal cell and its nearest compositional (not spatial) neighbor. The distribution of closest analogs within datasets indicates forest heterogeneity within each time period, while the search for closest analogs between datasets indicates whether contemporary forests lack analogs in pre-settlement forests, and vice versa. For the analog analyses, we compute Bray-Curtis distance between each 64km<sup>2</sup> cell in either the FIA or the PLS periods to all other cells within the other dataset (FIA to FIA, PLS to PLS), and between datasets (PLS to FIA and FIA to PLS), retaining only the minimum. For the FIA to FIA and PLS to PLS analyses, cells were not allowed to match to themselves.

The differences in sampling design and scale between the PLS and FIA datasets, described above, potentially affect between-era (e.g., Kronenfeld et al. 2010). The effects of differences in scale should be strongest in regions where there are few FIA plots per 64 km<sup>2</sup> cell, or where within-cell heterogeneity is high. For the analog analyses, this effect should increase the compositional differences between the FIA and PLS datasets. We test for the importance of this effect on our analog analyses via a sensitivity analysis in which we test whether dissimilarities between FIA and PLS gridcells are affected by the number of PLS plots per cell. We find a small effect, suggesting that our analyses are mainly sensitive to the compositional and structural processes operating on large spatial scales.

## Results:

### Data Standardization

The original PLS dataset contains 490818 corner points (excluding line and meander points), with NA points from Wisconsin, NA points from Minnesota and NA points from Michigan. Standardizing data and accounting for potential outliers, described above, removed approximately 1.5% points from the dataset, yielding a final total of 367540 points with estimates used in our analysis.

Rasterizing the PLS dataset to the Albers 64km<sup>2</sup> grid produces 7940 raster cells with data. Each cell contains between 1 and 94 corner points, with a mean of 62 ( $\sigma = 15$ ) and a median of 67 corners (Supplement 3). Cells with a low number of points were mainly near water bodies or along political boundaries such as the Canadian/Minnesota border, or southern Minnesota and Wisconsin borders. Only 2% of cells have fewer than 10 points per cell.

Species assignments to genera were rarely problematic. Only 0.00183% of PLS trees were assigned to the Unknown Tree category, largely consisting of corner trees for which taxon could not be interpreted, but for which diameter and azimuth data was recorded. A further 0.011% of trees were assigned to the “Other hardwood” taxon (e.g., hawthorn, “may cherry”, “white thorn”).

### Spatial Patterns of Settlement-Era Forest Composition: Taxa and PFTs

#### Stem Density, Basal Area and Biomass

The mean stem density for the region (Figure 3a) is 150 stems/ha. Stem density exclusive of prairie is 170 stems/ha and is 220 stems/ha when both prairie and savanna are excluded. The 95th percentile range is 0 - 420 stems/ha, and within-cell standard deviations between 0 and 440 stems/ha. Basal area in the domain (Figure 3c) has a 95th percentile range between 0 and 64 m<sup>2</sup>/ha, a mean of 22.2 m<sup>2</sup>/ha, within-cell standard deviations range from 0 to 77 m<sup>2</sup>/ha. Biomass ranges from 0 to 210 Mg/ha (Figure 3d), with cell level standard deviations between 0 and 570 Mg/ha. High within-cell standard deviations relative to mean values within cells for density, basal area and biomass indicate high levels of heterogeneity within cells, as expected for the PLS data, given its dispersed sampling design.

In the PLS data, stem density is lowest in the western and southwestern portions of the region, regions defined as prairie and savanna (Figure 3b, Table 3). When the Anderson and Anderson (1975) stem density thresholds (<47 stems/ha for Savanna, Table 3) are used, the extent of area classified as savanna is more limited in southern Wisconsin (Figure 3b) than in prior reconstructions (Curtis 1959, Bolliger et al. 2004, Rhemtulla et al. 2009b), despite generally low stem densities (Figure 3a). The highest stem densities occur in north-central Minnesota and in north-eastern Wisconsin (Figure 3a), indicating younger forests and/or regions of lower forest productivity. The joint controls of broad-scale climatic structuring and local hydrology controls on forest composition and density can be seen, particularly along the Minnesota River in south-western Minnesota, where a corridor of savanna is sustained in a region mostly occupied by prairie (Figure 3b).

Forest structure during the settlement era can be understood in part by examining the ratio of stem density to biomass, a measure that incorporates both tree size and stocking. Regions in northern Minnesota and northwestern Wisconsin have low biomass and high stem densities (Figure 4, red). This indicates the presence of young, small-diameter, even-aged stands, possibly due to frequent stand-replacing fire disturbance in the pre-EuroAmerican period. Fire-originated vegetation is supported by co-location with fire-prone landscapes in Wisconsin (Schulte et al. 2005). High-density, low-biomass regions also have shallower soils, colder climate, and resulting lower productivity. High-biomass values relative to stem density (Figure 4, blue) are found in Michigan and southern Wisconsin. These regions have higher proportions of deciduous species, with higher tree diameters than in northern Minnesota. This is likely due to higher soil productivity, and more temperate climates, with lower incidences of stand-replacing disturbance in the southern and eastern portions of the region.

Taxon composition within settlement-era forests is spatially structured along dominant gradients from south to north (deciduous dominated to conifer dominated forests) and from east to west (mixed wood forests to open prairie) (Figure 5). Oak is dominant in the south of the region, with an average composition of 21%, however, that proportion drops to 8% when only forested cells are considered, due to its prevalence in the savanna and prairie. Pine shows the opposite trend, with average composition of 14% and 17% in unforested and forested cells. Pine distributions represent three dominant taxa, *Pinus strobus*, *Pinus resinosa* and *Pinus banksiana*. These three species have overlapping but ecologically dissimilar distributions, occurring in close proximity in some regions, such as central Wisconsin, and are typically associated with sandy soils with low water availability. Other taxa with high average composition include maple (8%), birch (8%), tamarack (8%) and hemlock (6%).

For a number of taxa, proportions are linked to the total basal area within the cell. For 4 taxa, hemlock, birch, maple and cedar, taxon proportions are positively related to total basal area. For 17 taxa including oak, poplar, ironwood, tamarack and elm, high proportions are strongly associated with lower basal areas (Figures 3 and 5). This suggests that hemlock, birch, maple and cedar occurred in well-stocked forests, with higher average dbh. These taxa are most common in Michigan and in upper Wisconsin. Taxa with negative relationships are more common in the northwestern part of the domain.

Spruce in the PLS represents two species (*Picea glauca*, *Picea mariana*) with overlapping distributions, but complex site preferences (dry upland to wet-mesic for white spruce, and hydric for *P. mariana*, although in northern Minnesota *P. mariana* also occurs on uplands). Both cedar (*Thuja occidentalis*) and fir (*Abies balsamea*) are mono-specific genera in this region.

Northern hardwoods, such as yellow birch and sugar maple, and beech, are much less common in the lower peninsula of Michigan, and southern Wisconsin, except along Lake Michigan. Birch has extensive cover in the north, likely reflecting high pre-settlement proportions of yellow birch (*Betula alleghaniensis*) on mesic soils, and paper birch on sandy fire-prone soils and in northern Minnesota (birch proportions reach upwards of 34% in northeastern Minnesota). Hardwoods in the southwest, such as oak, elm, ironwood and basswood, are most typically mono-specific groupings, with the exception of oak, which comprises 7 species (see Supplementary Table 1). Hardwoods in the southwest are located primarily along the savanna and southern forest margins, or in the southern temperate deciduous forests. Finally, maple and poplar (aspen) have a broad regional distribution, occupying nearly the entire wooded domain. Poplar comprises four species in the region, while maple comprises five species (see Supplemental Material). Both hardwood classes, those limited to the southern portions of the region, and those with distributions across the domain, correspond to well-defined vegetation patterns for the region (Curtis 1959). Thus overlap among PFT distributions (Figure

6) emerges from the changing composition within the plant functional type from deciduous broadleaved species associated with the southern, deciduous dominated region, to broadleaved deciduous species associated with more northern regions in the upper Midwest.

### Comparison to FIA Composition

Modern forests (FIA) have higher stem densities (146.6549723 stems/ha,  $t_{1,5177} = 51.7850497$ ,  $p < 0.01$ ) and basal areas (-4.4849575 m<sup>2</sup>/ha,  $t_{1,5177} = -16.3932029$ ,  $p < 0.01$ ) than PLS forests, but overall, lower biomass (-8.6887885 Mg/ha,  $t_{1,5177} = -6.5262444$ ,  $p < 0.01$ ) than historical forests (Figure 7). We use only point pairs where both FIA and PLS data occur since non-forested regions are excluded from the FIA and as such. The similarity in biomass despite lower stem density and total basal area in the PLS data is surprising. Two likely factors are shifts in allometric scaling associated with changes in species composition, or a higher mean diameter of PLS trees (Figure 7d).

The PLS has a lower overall mean diameter than the FIA ( $\Delta_{diam} = -2.93$  cm, 95%CI from -17.35 to 8.18cm). FIA diameters are higher than PLS diameters in the northwestern parts of the domain (on average -6.49 cm higher), overlapping almost exactly with regions where we have shown low biomass-high density stands (Figure 4). At the same time, regions with high biomass and low density stands, in northeastern Wisconsin, and the Upper and Lower Peninsulas of Michigan, had higher average diameters during the PLS than in the FIA, on average 3.65 cm higher. Thus we are seeing an overall increase in tree size in the sub-boreal region and a decrease in temperate mixedwood forests, where we find tree species with much higher dbh:biomass ratios. This is coupled with declining variance in DBH across the domain (from 30.66 cm during the PLS to 30.66 cm in the FIA). Thus, the mechanism by which low density and basal area produce roughly equivalent biomass estimates between the FIA and PLS is likely due to the differential impacts of land clearance and subsequent forest management in the south east vs the northwest. The loss of high biomass southern hardwood forests is balanced by higher biomass in the northeast due to fire suppression and regeneration of hardwoods in the northwest. Declining diameters from the PLS to FIA are most strongly associated with higher abundances of poplar, ironwood and oak, while declining diameters are associated with maple and hemlock, further supporting the assertion that much of the loss in diameter, and, subsequently biomass, is occurring in southeastern mixedwood/hardwood forest, while diameter and biomass increases are occurring in the northwest.

Differences between FIA and PLS data in sampling design are unlikely to be a factor; these differences are expected to affect how these datasets sample local- to landscape-scale heterogeneity, but should not affect the overall trends between datasets. Differences in variability introduce noise into the relationship, but given the large number of samples used here, the trends should be robust.

### Compositional Changes Between PLS and FIA Forests

Both the PLS- and FIA-era compositional data show similar patterns of within-dataset dissimilarity, with the highest dissimilarities found in central Minnesota and northwestern Wisconsin. High within-PLS dissimilarities are associated with high proportions of maple, birch and fir while high within-FIA dissimilarities are associated with high proportions of hemlock, cedar and fir. Dissimilarity values in the FIA dataset are less spatially structured than in the PLSS. Moran's I for dissimilarities within the FIA ( $I_{FIA} = 0.1979074$ ,  $p < 0.001$ ) are lower than the dissimilarities within the PLSS ( $I_{PLSS} = 0.4951891$ ,  $p < 0.001$ ), suggesting lower spatial autocorrelation in the FIA dataset. Cells with identical pairs represent 5.6% of the PLS cells and 7.4 of FIA cells. Identical cells in the PLS are largely located along the southern margin and most (69%) are composed entirely of oak. Cells in the FIA with identical neighbors are composed of either pure oak (19%), pure poplar (26%) or pure ash (14%).

There is a small but significant relationship ( $F_{1,5964} = 920$ , NA,  $p < 0.001$ ) between the number of FIA plots and within-FIA dissimilarity. The relationship accounts for 10% of total variance and estimates an increase of  $\delta_d = 0.0134277$  for every FIA plot within a cell. This increase represents only 3.1% of the total range of dissimilarity values for the FIA data. There is a gradient of species richness that is co-linear with the number

of FIA plots within a cell, where plot number increases from open forest in the south-west to closed canopy, mixed forest in the Upper Peninsula of Michigan. Hence, differences in within- and between-cell variability between the PLS and FIA datasets seem to be having only a minor effect on these regional-scale dissimilarity analyses.

We define no-analog communities as those whose nearest neighbour is beyond the 95%ile for dissimilarities within a particular dataset. In the PLS dataset, forests that have no modern analogs are defined as “lost forests”, while forest types in the FIA with no past analogs are defined as “novel forests”. More than 25% of PLS sites have no analogue in the FIA dataset (‘lost forests’; PLS-FIA dissimilarity, Figure 8c), while 29% of FIA sites have no analogue in the PLS data (‘novel forests’; FIA-PLS dissimilarity, Figure 8d). Lost forests show strong spatial coherence, centered on the “Tension Zone” (Curtis 1959), the ecotone between deciduous forests and hemlock-dominated mixed forest (Figure 5).

Lost forests are drawn from across the domain, and show strong ecological and spatial coherence (Figure 8c).

Forest classes generally fall into five classes: Hemlock-Birch-Cedar/juniper-Maple accounts for 28.3% of all lost forests and 7.85% of the total region. This forest type is largely found in northern Minnesota, extending southward to central Minnesota and into Wisconsin and along the Upper Peninsula of Michigan, as well as in scattered locations on the Lower Peninsula of Michigan. The forest likely represents a mesic to hydric forest assemblage. Modern forests overlapping this lost type are largely composed of poplar, oak and maple. Oak-Elm-Maple-Basswood accounts for 20.9% of all lost forests and 5.8% of the total region. The region is centered largely within savanna and prairie forest margin, both in south-central Minnesota and in eastern Wisconsin, but, interestingly is largely absent from the Driftless area of southwestern Wisconsin. This lost forest type has been predominantly replaced by oak, ash and maple. Within these forests oak has increased (from 18 - 24%) while elm has declined (from 18% to 10%).

Pine-Birch-Tamarack accounts for 20.2% of all lost forests and 5.59% of the total region. This forest covers portions of the Upper Peninsula and the western Lower Peninsula of Michigan, as well as portions of north central Wisconsin. In these forests hemlock has declined from 26% to only 4%, replaced by maple (increasing from 7% to 22%) and poplar which increases from 2% to 14%. This shift from older forest types to early seral forests is seen in other PLS forests. Tamarack-Birch-Spruce accounts for 18.2% of all lost forests and 5.04% of the total region. This forest type was likely dominated by late seral yellow birch (a mean of 26% composition, declining to 9%), replaced largely by maple (from 15 - 25%). Poplar increases from 2% to 14% in the FIA, again indicating a shift to earlier seral forests in the FIA. Hemlock is almost entirely lost from the forests, declining from 12% to 3% in the FIA.

Lastly, Beech-Hemlock-Maple accounts for 12.5% of all lost forests and 3.45% of the total region. This forest type is found exclusively on the central, western shore of Lake Michigan and in the Lower Peninsula, in part due to the limited geographic range of Beech in the PLS dataset (Figure 5). Beech is almost entirely excluded from the modern forests in this region, declining from a PLS mean of 36% to an FIA mean of 4%. Pine in the region increases from 9% to 16%, while maple increases from 14 - 24%.

On average lost forests contain higher proportions of ironwood ( $r = 0.2$ ), beech ( $r = 0.2$ ), birch ( $r = 0.19$ ) and hemlock ( $r = 0.19$ ) than the average PLS forest, and lower proportions of oak ( $r = -0.28$ ), poplar ( $r = -0.14$ ), and pine ( $r = -0.11$ ).

The distribution of novel ecosystems (Figure 8d) is spatially diffuse relative the lost forest of the PLS and the forest types are dominated by monotypic forests. FIA novel forest types have a more uneven distribution in proportion than the PLS lost forests.

By far the largest novel forest type is Maple, which accounts for 31% of all novel forests and 8.06% of the total region. This forest type is associated with proportions of Maple near 40%, and appears to replace the lost 28.3 forests, although the distribution of 31 forests is shifted slightly northward and eastward of the lost forests.

Oak-Pine, accounts for 22.8% of all novel forests and 5.93% of the total region. This forest type is dominated by early seral taxa (poplar) and is widely distributed across the region, representing a homogenous, early seral forest type, likely associated with more mesic sites. Poplar-Maple-Cedar/juniper accounts for 21.6% of all novel forests and 5.62% of the total region. This forest type replaces the largely monotypic oak savanna

in places, but represents a novel forest assemblage, likely because of the co-dominance of pine and oak in these sites and the presence of maple, basswood and poplar as secondary cover. This forest type is also present in the Lower Peninsula and along the Michigan-Wisconsin border, likely representing a different set of oak and pine species than in the southern forests. Ash accounts for 14.5% of all novel forests and 3.77% of the total region. This monotypic grouping again shows a pattern of broad distribution across the region, associated with Ash percentages near 40%, with smaller components of poplar and maple. The smallest group, Basswood-Maple, accounts for only 31% of all novel forests and 5.93% of the total region. These forests are present only in the far north, and particularly in the far northeastern portions of the region.

Overall, novel forests are associated with higher proportions of maple ( $r = 0.1$ ), ash ( $r = 0.1$ ) and basswood ( $r = 0.11$ ), and lower proportions of oak ( $r = -0.28$ ), and pine ( $r = -0.11$ ). This analysis suggests that the loss of particular forest types associated with post-settlement land use was concentrated in mesic deciduous forests and the ecotonal transition between southern and northern hardwood forests, while the gains in novelty were more dispersed.

To understand how the ecotone has been transformed by post-settlement land use, we constructed two transects of the FIA and PLS data (Figure 10a), and fitted GAM models to genus abundances along these transects. Transect One (T1) runs from northern prairie (in northern Minnesota) to southern deciduous savanna in southeastern Wisconsin, while Transect Two (T2) runs from southern prairie in southwestern Minnesota to northern mixedwood forest in the Upper Peninsula of Michigan.

For T1, GAM models show significant differences (using AIC) in the curves fit to tamarack, pine, birch, oak, poplar and spruce between PLS and FIA data, but not for elm, maple or hemlock, which is almost entirely absent along the transect (Figures 10b and c). Pine used to be a major component of the tension zone, reaching proportions of up to 80% in north central Wisconsin (Figure but has declined due to logging and subsequent regeneration of other taxa. Increases in pine in southeastern Wisconsin are likely due to the cultivation of pine plantations in the region. Significant changes in taxon composition between PLS and FIA data are also apparent in T2, particularly for tamarack, pine, birch, maple, oak, and hemlock. Oak is almost completely eliminated from the central to western portions of the transect in the FIA data, largely due to land conversion to agriculture. The eastern portion of T2 shows a shift from a landscape dominated by multiple taxa – pine, birch, maple and hemlock – to one dominated by maple, along with lower proportions of poplar (T2, FIA: Figure 9d and e).

Contemporary forests show broader homogenization and increased heterogeneity (evidenced by the lower FIA-FIA Moran’s  $I$  estimates for near-neighbor distances) at a local scale in the region. Homogenization is evident across T1, where Bray-Curtis dissimilarity between adjacent cells declines from the PLSS to the FIA ( $\delta_{beta} = -0.22$ ,  $t_{113} = -7.93$ ,  $p < 0.001$ ), mirroring declines in the pine barrens between the 1950s and the present (2014). The PLS shows strong differentiation in the central region of T2 where maple-pine-oak shifts to pine-poplar-birch forest (Figure 9d). This sharp ecotone is not apparent in the FIA data, which shows gradual and blurred changes in species composition across the ecotone (Figure 9e).  $\beta$ -diversity along T2 is lower in the FIA than in the PLSS ( $\delta_{beta} = -0.19$ ,  $t_{65} = -7.34$ ,  $p < 0.01$ ), indicating higher heterogeneity in the PLS data at the 64 km<sup>2</sup> meso-scale.

Across the entire domain,  $\beta$  diversity is lower in the FIA than in the PLS ( $\Delta_{beta} = -0.172$ ,  $t_{1.3e7} = 2480$ ,  $p < 0.001$ ), lending support to the hypothesis of overall homogenization. Differences in sampling design between PLS and FIA data cannot explain this homogenization, since its effect would have been expected to increase  $\beta$ -diversity along linear transects and at larger spatial scales.

## Discussion

Methodological advances of the current work include 1) the systematic standardization of PLS data to enable mapping at broad spatial extent and high spatial resolution, 2) the use of spatially varying correction factors to accommodate variations among surveyors in sampling design, and 3) parallel analysis of FIA datasets to enable comparisons of forest composition and structure between contemporary and historical time periods. This approach is currently being extended to TPS and PLS datasets across the north-central and northeastern

US, with the goal of providing consistent reconstructions of forest composition and structure for northeastern US forests at the time of Euroamerican forests.

Results show clear signs of increased homogenization at local and regional scales and decreased spatial structure in vegetation assemblages. Decreased  $\beta$  diversity along regional transects indicates homogenization at meso-scales of 100s of km<sup>2</sup>, while the overall reduction in Moran's I for dissimilarity in the FIA indicates a regional reduction in heterogeneity on the scale of 1000s of km<sup>2</sup>. This homogenization also causes the selective loss or weakening of major vegetation ecotones, particularly in central Wisconsin, and the development of novel species assemblages across the region.

All datasets and analytic codes presented here are publicly available and open source (<http://github.com/SimonGoring/WitnessTrees>), with the goal of enabling further analyses of ecological patterns across the region and the effects of post-settlement land use on forest composition and structure. Our results support the consensus that robust estimates of pre-settlement forest composition and structure can be obtained from PLS data (e.g., Wisconsin: Schulte et al. 2002, Iowa: Rayburn and Schulte 2009, California: Williams and Baker 2011, Oregon: Duren et al. 2012). Patterns of density, basal area and biomass are roughly equivalent to previous estimates (Schulte et al. 2007, Rhemtulla et al. 2009a). Our results for stem density are lower than those estimated by Hanberry *et al.* (Hanberry et al. 2012a) for eastern Minnesota, but density and basal area are similar to those in the northern Lower Peninsula of Michigan (Leahy and Pregitzer 2003) and biomass estimates are in line with estimates of aboveground carbon for Wisconsin (Rhemtulla et al. 2009a).

Anthropogenic shifts in forest composition over decades and centuries seen here and elsewhere (Cogbill et al. 2002, Thompson et al. 2013) are embedded within a set of interacting systems that operate on multiple scales of space and time (macrosystems, *sensu* Heffernan et al. 2014). Combining regional historical baselines, long term ecological studies and high frequency analyses can reveal complex responses to climate change at local and regional scales (Goffman et al. 2012). Estimates of pre-settlement forest composition and structure are critical to understanding the processes that govern forest dynamics because they represent a snapshot of the landscape prior to major Euro-American land-use conversion. Pre-settlement vegetation provides an opportunity to test forest-climate relationships prior to land-use conversion and to test dynamic vegetation models in a data assimilation framework (e.g., Hartig et al. 2012). For these reason, the widespread loss of regional forest associations common in the PLS (Figure 8d), and the rapid rise of novel forest assemblages (Figure 8e) have important implications for our ability to understand ecological responses to changing climate. The loss of these forests implies that the modern understanding of forest cover, climate relationships, realized and potential niches and species associations may be strongly biased toward a single state, even though 38% of the total regional cover is novel relative to forests only two centuries ago.

Beyond shifts in composition at a meso-scale, the broader shifts in ecotones can strongly impact models of species responses and co-occurrence on the landscape. For example, the heterogeneity, distribution, and control of savanna-forest boundaries (Staver et al. 2011) is of particular interest to ecologists and modelers given the ecological implications of current woody encroachment on savanna ecosystems (Ratajczak et al. 2012). Declines in landscape heterogeneity may also strongly affect ecosystem models, and predictions of future change. Recent work using the FLUXNET tower network has shown that energy budgets are strongly related to landscape measures of heterogeneity (Stoy et al. 2013). Our data show higher levels of heterogeneity at mesoscales during the pre-settlement era, and greater fine scaled turnover along transects. Lower  $\beta$  diversity shown here and elsewhere (Li and Waller 2014) indicate increasing heterogeneity at a very large spatial scale, and the loss of resolution along major historical ecotones. Thus analysis of the processes governing vegetation heterogeneity and ecotones may inadvertently and substantially incorporate anthropogenic processes.

These

for pollen-based vegetation reconstructions for time periods prior to the historic record. Many papers have used calibration datasets comprised of modern pollen samples to build transfer functions for inferring past climates and vegetation from fossil pollen records (Jacques et al. 2008, Goring et al. 2009, Paciorek and McLachlan 2009, Birks et al. 2010). However, modern pollen datasets are potentially confounded by recent land use, which can alter paleoclimatic reconstructions (Jacques et al. 2008). By linking pollen and vegetation at modern and historical periods we develop capacity to provide compositional datasets at broader spatio-temporal scales, providing more data for model validation and improvement. Ultimately, it should be possible to assimilate these empirical reconstructions of past vegetation with dynamic vegetation models

in order to infer forest composition and biomass during past climate changes. Data assimilation, however, requires assessment of observational and model uncertainty in the data sources used for data assimilation. Spatiotemporal models of uncertainty are being developed for the compositional data (Thurman et al. in prep) and biomass data (Feng *et al.* in prep.).

Ultimately the pre-settlement vegetation data present an opportunity to develop and refine statistical and mechanistic models of terrestrial vegetation that can take multiple structural and compositional forest attributes into account. The future development of uncertainty estimates for the data remains an opportunity that can help integrate pre-settlement estimates of composition and structure into a data assimilation framework to build more complete and more accurate reconstructions of past vegetation dynamics, and to help improve predictions of future vegetation under global change scenarios.

**Table 1.** *Correction values based on plot level survey design using state, year, and location within township as a basis for assignment. Years reported represent the upper bound for each set of survey years. Internal points are points within the township, external points are on the township boundary; no sampling occurred outside of a township boundary so plots were limited to half of the space for internal points. Townships are divided into Section and Quarter Sections, at most section points and some quarter section points, survey instructions indicated four trees were to be sampled, these were ‘2nQ’ plots, whereas others surveyed only two points in adjacent plot halves (‘P’ plots).*

Spruce	-2.08	2.33	Spruce

**Table 3.** Forest classification scheme used in this paper for comparison between pre-settlement forests and the Haxeltine and Prentice (1996) potential vegetation classes represented in Ramankutty and Foley (Ramankutty and Foley 1999). Plant functional types (PFTs) for grasslands (CG, grassland; Non-Tree samples in the PLS), broad leafed deciduous taxa (BDT) and needleleaved evergreen taxa (NET) are used, but leaf area index used in Haxeltine and Prentice (1996) is replaced by stem density classes from Anderson and Anderson (Anderson and Anderson 1975).

Forest Class	Haxeltine & Prentice Rules	Current Study
Prairie	Dominant PFT CG, LAI > 0.4	Stem dens. < 0.5 stem/ha
Savanna	Dominant PFT CG, LAI > 0.6	1 < Stem dens. < 47 stems/ha
Temperate Deciduous	Dominant PFT BDT, LAI > 2.5	Stem dens. > 48 stems/ha, BDT > 70% com
Temperate Conifer	Dominant PFT (NET + NDT), LAI > 2.5	Stem dens. > 47 stems/ha, NET + NDT >
Mixedwood	Both BDT (LAI > 1.5) & NET (LAI > 2.5) present	Stem dens. > 47 stems/ha, BDT & NET bo

**Table 4.** Classification proportions, patch size and edge cell proportion for various classification schemes used with the Public Land Survey data. All patch size estimates are in 1000s of km<sup>2</sup>.

Classification Metric	Prairie	Savanna	Temperate Deciduous	Temperate Evergreen	Mixed Wood	Mean
Ramankutty and Foley (1999)	86	63	9	50	241	181

Classification Metric	Prairie	Savanna	Temperate Deciduous	Temperate Evergreen	Mixed Wood	Mean
PLS Data	51	90	83	149	100	37

**Figure 1.** The domain of the Public Land Survey investigated in this study. The broad domain includes Minnesota, Wisconsin and the upper two thirds of Michigan state.

**Figure 2.** Correction factors for  $\zeta$  in the PLS data, and the associated distribution of azimuths for each  $\zeta$  value, by panel. High peaks represent midpoints for quadrants where azimuth is defined as e.g., NE or SW. Greater differences between cardinal directions and other azimuths result in higher  $\zeta$  values, excluding the peaked values.

**Figure 3.** Total stem density (a) in the Upper Midwest, along with forest type classification (b) based on PLS data and the stem density thresholds defined by Anderson and Anderson (1975); Table 3). Fine lines represent major rivers. To a first order, basal area (c) and biomass (d) show similar patterns to stem density (but see Figure 4).

**Figure 4.** Maps of the ratio between biomass and stem density as an indicator of forest structure. Regions with high stem density to biomass ratios (blue) indicate dense stands of smaller trees, while regions with low stem density to biomass ratios (red) indicate larger trees with wider spacings.

**Figure 5.** Forest composition (%) for the 15 most abundant tree taxa. The scale is drawn using a square-root transform to emphasize low abundances. Shading of the bar above individual taxon maps indicates plant functional type assignments (dark gray: needleleafed deciduous; light gray: needleleafed evergreen; white: broadleafed deciduous).

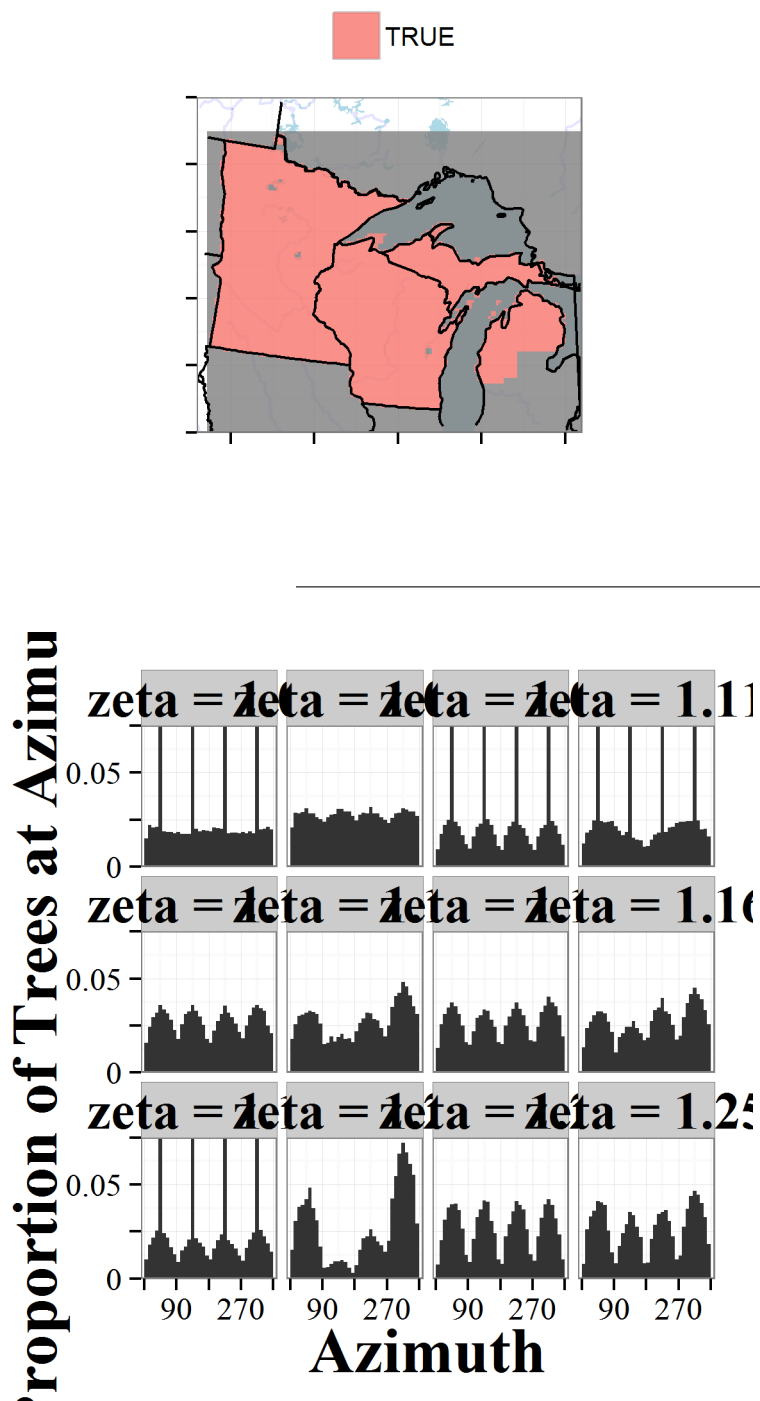

**Figure 6.** Proportional distribution of Plant Functional Types (PFTs) in the upper Midwest from PLS data, for broadleaved deciduous trees (BDT), needleleafed deciduous trees (NDT), and needleleafed evergreen trees (NET). Distributions are shown as proportions relative to total basal area, total biomass, and composition (Figure 3). The grassland PFT is mapped onto non-tree cells with the assumption that if trees were available surveyors would have sampled them.

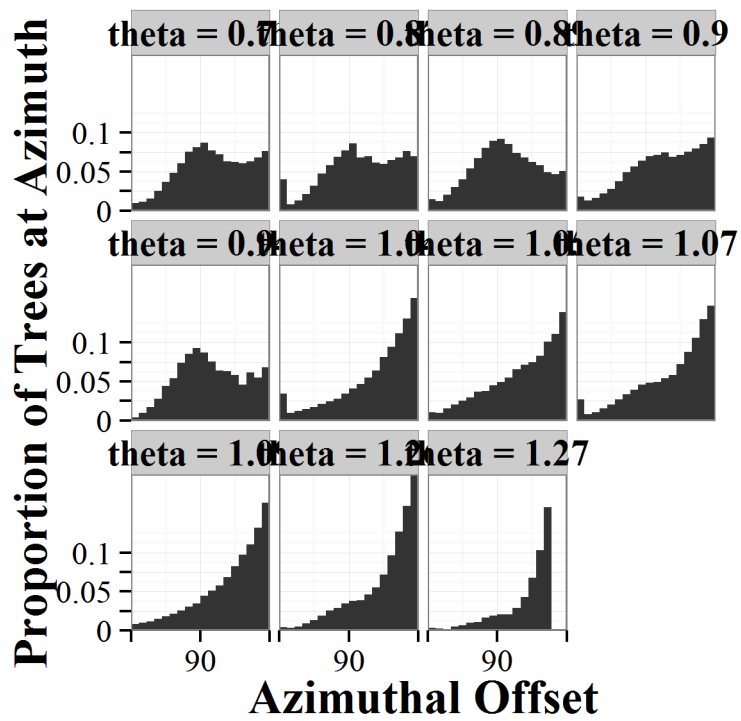

**Figure 7.** The relationship between average stem density, total basal area and biomass values in the PLS and FIA datasets. Stem density and total basal area are higher in the FIA than in the PLS, however average cell biomass is higher in the PLS.

**Figure 8.** Minimum dissimilarity maps. Distributions of minimum dissimilarities (a) show similar distributions within time periods, and higher overall dissimilarities between time periods. Cells with a high minimum dissimilarity lack close compositional analogs to other cells in the reference dataset. Compositional heterogeneity within the PLS (b) and FIA data (c) are high, with lower spatial structure during the FIA period. Between time-period dissimilarities for PLS and FIA data highlight PLS forests with no close analogs in the FIA data (d, ‘lost forests’; PLS-FIA) and FIA forests with no close PLS analogs (e, ‘novel forests’; FIA-PLS).

**Figure 9.** Transects across the region show clear changes in the ecotonal strength. Ecotones in the pre-settlement era were stronger in the past than they are in the present. Fitted curves represent smoothed estimates across the transects using Generalized Additive Models using beta fits.

Currently Unscripted Plot Angle pairs for theta.
